Abstract

Recent discussion on invasive species has invigorated the debate on strategies to manage these species. *Lantana camara* L., a shrub native to the American tropics, has become one of the worst weeds in recorded history. In Australia, India and South Africa, *Lantana* has become very widespread occupying millions of hectares of land. Here, we examine historical records to reconstruct invasion and management of *Lantana* over two centuries and ask: Can we fight the spread of invasive species or do we need to develop strategies for their adaptive management? We carried out extensive research of historical records constituting over 75% of records on invasion and management of this species in the three countries. The records indicate that governments in Australia, India and South Africa have taken aggressive measures to eradicate *Lantana* over the last two centuries, but these efforts have been largely unsuccessful. We found that despite control measures, the invasion trajectory of *Lantana* has continued upwards and that post-war land-use change might have been a possible trigger for this spread. A large majority of studies on invasive species address timescales of less than one year; and even fewer address timescales of >10 years. An understanding of species invasions over long time-scales is of paramount importance. While archival records may give only a partial picture of the spread and management of invasive species, in the absence of any other long-term dataset on the ecology of *Lantana*, our study provides an important insight into its invasion, spread and management over two centuries and across three continents. While the established paradigm is to expend available resources on attempting to eradicate invasive species, our findings suggest that in the future, conservationists will need to develop strategies for their adaptive management rather than fighting a losing battle.

Introduction

Biologists, ecologists and conservationists disagree on the best way to respond to invasive species [1–5]. *Lantana camara* L. (referred to as *Lantana* from here on), a shrub native to the American tropics, has become one of the worst weeds in the world. *Lantana* was introduced in early-mid 19th century in tropical parts of Africa, Asia and Oceania as an ornamental garden plant [6–8]. Global Invasive Species Information Network now identifies *Lantana* among the top ten invasive species in the world based on the number of countries where these species are considered invasive [9] and IUCN's list of world's 100 worst alien invasive species includes *Lantana* [10]. In Australia, India and South Africa, *Lantana* has been reported as a widespread weed [11,12]. Management of invasive species is highlighted as a major task facing conservation planners [13,14] and accordingly governments and some non-governmental actors in these countries are continuing to take aggressive measures to attempt to eradicate *Lantana*. However, the knowledge of long-term trends of invasive species is very limited due to the lack of historical records. The

majority of studies on invasive species address timescales of less than one year; and fewer than 10% address timescales of >10 years [15]. Strayer et al. [15] examined *c.* 200 studies published between 2001 and 2005 in ecological journals and concluded that “most studies of the effects of invasive species have been brief and lack a temporal context” (p. 645). An understanding of species invasions over long time-scales is therefore of paramount importance [16]. Here, we examine the invasion and adaptive management of *Lantana* over two centuries using historical records. The majority of these records were held in the Bodleian Libraries at Oxford, and a few in government libraries in South India. These consisted primarily of regional and national forestry reports and journals, together with selected botanical records, conference reports and government publications.

Spread of *Lantana* and its current status

Current estimates suggest that *Lantana* has invaded more than 5 million ha in Australia, 13 million ha in India and 2 million ha in South Africa [17–20]. Reports of this invasive from the 19th and 20th centuries from these three countries give an insight into the

spread of *Lantana* [21,22]. Its introduction to botanical gardens in European colonies made it a popular garden and hedge plant in the early 19th century [23–25]. Soon afterwards, e.g. in Australia in the 1850s, *Lantana* was even considered ‘naturalised’ in some reports [26]. In others, it was mentioned as merely present, e.g. [27], but was not perceived as a problem. It was only in the late 19th century in Australia [28] and India [29], and mid-20th century in South Africa (reported in [30]), that *Lantana* was considered as an invasive or noxious weed. Active management of *Lantana* began in the early 20th century in Australia, e.g. [31], and India, e.g. [32], and in the late 20th century in South Africa, e.g. [33]. Various methods of controlling *Lantana* were trialled throughout the mid-20th century, including control with fire, mechanical removal, chemical and biological control; and reports suggest that these methods or their combination was successful in some regions, e.g. [33–35]. However, reports from the latter part of the 20th century suggest that *Lantana* continued to spread despite management [36–38].

Efforts to eradicate *Lantana*

Historical records indicate that the drive to eradicate *Lantana* demanded substantial resources and manpower throughout the 19th and 20th centuries. A combination of fire, mechanical and biological control was used in India as early as 1921 [32]. In Australia control of *Lantana* is reported in the early part of the 20th century and in South Africa in the late-20th century, but the number of reports about control increase in the 1970s in Australia [39] and in South Africa [40] suggesting that substantial effort was made to eradicate *Lantana* around this time. Reports from Australia suggest that emphasis was on biocontrol – to reduce *Lantana* to a level below a threshold of impact. For example, the Forestry Commission of New South Wales reports from 1959 through to 1983 provide details on insects used in biocontrol and their impact [41]. In South Africa, on the other hand, the emphasis was on mechanical removal. For example, the Department of Forestry [42] reports the heavy cost of removal in 1981 and a wide variety of methods used including mowing, hoeing out, drying and burning. Despite substantial weed management efforts, *Lantana* still remains a major concern in Australia, India and South Africa [22].

Here we reconstruct invasion trajectories of *Lantana* in Australia, India and South Africa based on historical records from the 19th and 20th centuries. We ask: (a) What were the drivers of spread of *Lantana*? (b) How rapidly did *Lantana* spread and why? (c) What attempts were made to control the spread of *Lantana* and were they successful? In answering these questions, and in the absence of a review protocol to study invasive species from historical records, we develop a novel method to reconstruct invasion trajectories.

Results

The spatial maps of point data on *Lantana* spread suggest that the early invasion is recorded around towns and cities; and it subsequently spreads into the wider countryside (Fig. 1A, 1B, 1C). For example, records of invasion in Australia suggest that in the 1920s *Lantana* spread in areas around Brisbane and Cairns, and subsequently in the countryside along the Queensland coast. In South Africa, initial records of invasion are from Durban and Cape Town, while later records suggest the spread of *Lantana* along the eastern and southern coast. Our Indian data are mainly focused around the Nilgiri Biosphere Reserve in South India and are at a much finer regional scale. However, even at this scale, the records suggest initial spread of *Lantana* around cities such as

Ooty, followed by its invasion in to the wider countryside, although this spatial pattern is not as clear-cut as in Australia or in South Africa.

A quantitative assessment of the scale of invasion of *Lantana* gives an insight into its invasion trajectory between 1800 and the present day. The overall trend of *Lantana* invasion in Australia, India and South Africa is similar showing a consistent increase throughout the time period in question (Fig. 2A). There are, however, some regional differences. The time of introduction is different across the countries, with *Lantana* being introduced to India shortly after 1800, to Australia shortly before 1850 and to South Africa shortly after 1850. *Lantana* is soon considered a ‘weed’ in historical records, but the need for its management appears to arise in India and Australia only in the 1920s, while in South Africa, management is not introduced until after the 1950s. The management of *Lantana* continues thereafter, but recent reports from each country indicate that this plant is spreading despite management efforts to eradicate or control it. There is a small reversal in the trend in India around 2000s, reflected by the fact that management maintains status quo and, significantly, managers no longer mention eradication of *Lantana* as a goal but rather only mitigative management for control of the plant such that it does not adversely affect wildlife. However, subsequent reports suggest that *Lantana* is continuing to spread despite such management.

Lantana invasion trajectory shows its highest rate of change in the 1920s in Australia and India (Fig. 2B). In South Africa, the highest rate of change is around the 1960s which coincides with another surge in reports of the species in Australia around the same time. The rate of change in India falls momentarily just before 2000s, probably reflecting the shift in focus from management for eradication to management for control, but increases subsequently.

Control measures of *Lantana* include fire, mechanical removal, chemical and biological control or their combination (Fig. 3). While the peak in control effort in India is seen in the 1910s, in Australia and South Africa, the peak is seen in the 1970s. Biocontrol appears to be the most prominent method in Australia during this time; and in South Africa reports suggest mechanical removal as preferred method. In India, a combination of methods except chemical control is used with a majority of reports indicating mechanical removal – including the use of domestic elephants to uproot *Lantana* – as the preferred method.

A bioclimatic niche model of *Lantana* (Fig. 4) indicates that a substantially greater area than *Lantana*’s current distribution falls within its bioclimatic envelope. This includes most of the sub-Saharan Africa, most of peninsular India and large tracts along the northern and eastern coast of Australia, as well as South East Asia. In addition, parts of the Mediterranean basin and coastal parts of Western Europe also fall within *Lantana*’s bioclimatic envelope.

Discussion

The effect of *Lantana* on ecosystems

While native to the Americas, *Lantana* was brought to Europe in the 16th century and since that date it has been subjected to horticultural improvement through selection of traits and hybridisation, leading to the creation of 630 named cultivars and variants. This genetically diverse artificial species complex was the source of introductions to India, Australia and South Africa [6]. This plasticity has enabled it to adapt to a wide variety of habitats – from sea level to 1800 m or more [43,44]. *Lantana* grows in tropical, subtropical and temperate climates, with mean annual rainfall of <1000–>4000 mm [45]. *Lantana* can also aggressively

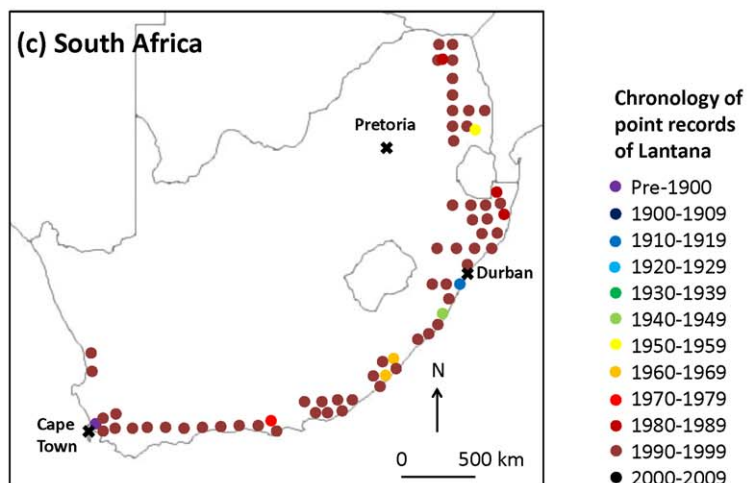

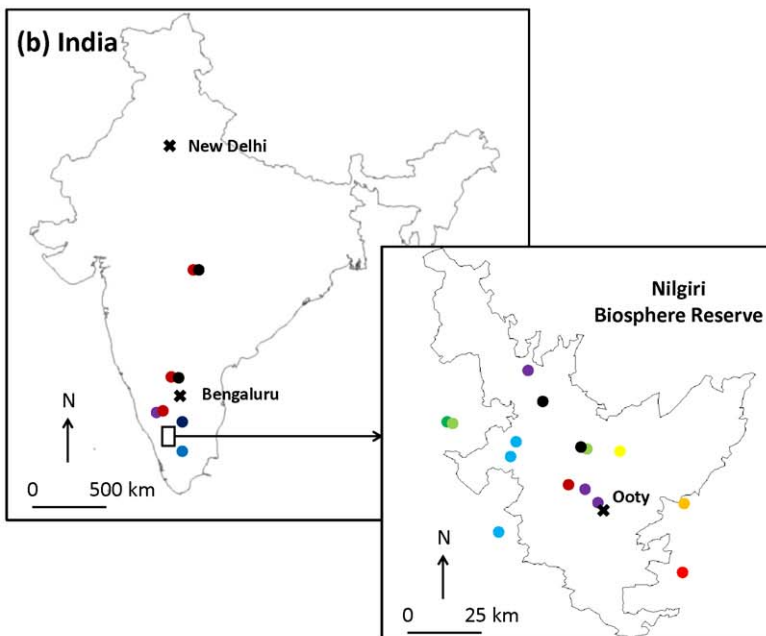

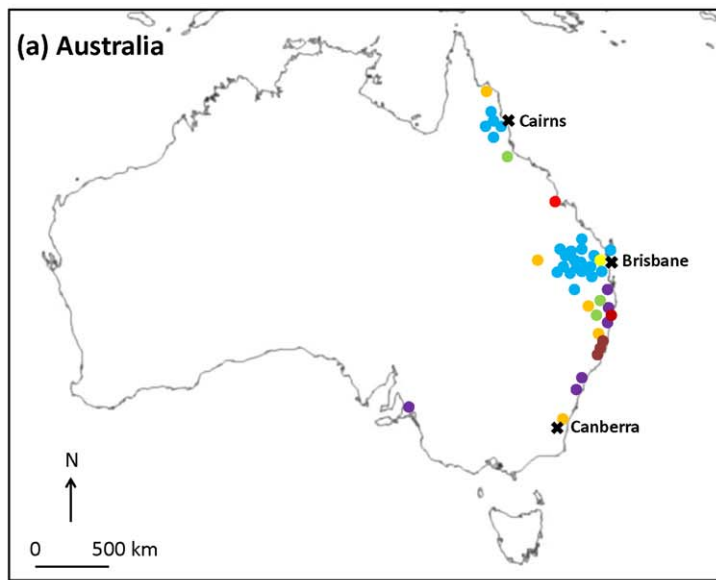

Figure 1. Spatial distribution of Lantana records from Australia, India and South Africa based on historical reports of its spread, management and control. A total of 42 points records are mapped from (a) Australia, 23 from (b) India and 10 from (c) South Africa. Records from South Africa between 1990–1999 come from one source [97]. Early records suggest spread of Lantana around towns and cities where it was first introduced. Later records indicate its spread in the wider countryside despite management. Most Indian records come from Nilgiri Biosphere Reserve where a more regional analysis of Lantana invasion was carried out. doi:10.1371/journal.pone.0032407.g001

compete for surface-soil nutrients and water [46], is allelopathic and hinders seedling recruitment and growth of other plants in its vicinity [47–50], it produces abundant seed that is dispersed large distances by birds and water, and is able to form dense stands under favourable conditions, enabling it to quickly dominate native vegetation [8,51,52]. These properties have made Lantana one of the most successful weeds, which can dramatically transform ecosystems. Studies suggest that Lantana invasion affects local biodiversity and all four categories of ecosystem services – provisioning, regulating, supporting and cultural [53]. For example, Lantana is known to pose serious threat to biodiversity in several World Heritage sites and Endangered Ecological Communities in Australia (e.g. rainforest of northern Queensland, Fraser Island and the Greater Blue Mountains), the Fynbos of South Africa, and biodiversity hotspots in India (e.g. the Western Ghats and Eastern Himalayas) [12,54,55]. Furthermore, Lantana is toxic to livestock and harbours the tsetse fly, the vector

of African sleeping sickness, and malarial mosquito [12]. It is also known to affect economic viability of 14 major crops around the world including coffee, tea, rice, cotton, oil palm, coconut and sugarcane, in part due to its allelopathic properties, which reduce productivity of crop plants [22].

Invasion trajectory and management effort

Our results suggest that Lantana has continued an upward trajectory of spread and invasion in Australia, India and South Africa. One striking feature of this invasion trajectory is its spread despite intensive management. For example, in the early 1980s Lantana had invaded about 2.2 million hectares of forest plantations, watercourses and savannah in South Africa and mechanical and chemical control had little effect on this invasive species [43]. Similarly, in India all efforts using biological control in the mid-1980s had failed and Lantana was still spreading [38]. In an assessment of invasive species in Queensland, Australia in

Figure 2. Invasion trajectories of Lantana in Australia, India and South Africa. (a) Historical records of Lantana spread, control and management are scored on a scale of 1–7: (1) first introduced; (2) present, but not a problem; (3) considered weed, invasive or noxious plant; (4) management intensified; (5) management reported effective in some areas; (6) continuation of same management strategy; (7) Lantana seen to be spreading in spite of management. (b) Rate of change is calculated as increase per year in the state of invasion, measured on the seven-point scale. doi:10.1371/journal.pone.0032407.g002

Figure 3. Methods used for control, management and eradication of Lantana during the 20th century. A variety of methods are reported in historical records: fire, mechanical removal, chemical and biological control and a combination of these four measures. A total of 84 reports on control measures are available from Australia, 31 from South Africa and 24 from India. For parity in comparison across the three countries, frequencies of reports are expressed as percentages.
doi:10.1371/journal.pone.0032407.g003

2003 Lantana was ranked the most invasive weed [56]. It is also evident that considerable resources were spent on Lantana control and management in all three countries while the invasion trajectory continued to rise upwards. In 1973, for example, the cost of Lantana control in Queensland, Australia was estimated at c.A \$1 M (US \$1 M) per year [57]. In South Africa, the cost of chemical poisoning to control Lantana was estimated at R 1.7 M (US \$ 250,000) per year in 1999 [58]. Estimates from India suggest that the present cost of Lantana control is approximately INR 9000 (US \$ 200) per hectare [59]. In addition, substantial opportunity costs of Lantana invasion are reported in the literature; for example, Lantana's global infestation of millions of hectares of grazing land [22,60]. A study of the grazing sector in Queensland, Australia suggested that in 2007 this sector incurred opportunity costs of A \$ 121 M (US \$ 121 M) due to Lantana invasion [61] in comparison with A \$ 3 M (US \$ 3 M) per year loss recorded for the same sector in 1985 [60]. Similar concerns have also been reported from India [22].

Rate of change and drivers of spread

Our invasion trajectories of Lantana across three continents suggest that there were episodes of rapid change. In Australia, Lantana was first introduced to the old Botanical Gardens in Adelaide, South Australia, and due to its popularity as garden

plant multiple introductions followed, mainly in New South Wales and Queensland [62,63]. In India, Lantana is known to have been introduced in 1807 in Kolkata botanical gardens [64] while in the Nilgiris, where we focused our investigation, Lantana was mentioned for the first time by Hough in 1829 [24]. In South Africa, the first introduction did not take place until 1858, when it was introduced to Cape Town [25,65]. The invasion trajectory of Lantana in Australia and India shows a rapid rate of change around mid-1920s. This was shortly after the end of World War I, when a period of post-war economic depression occurred [66]. Both Australia and India experienced rapid land use change, mining and exploitation of other natural resources at this time [67]. This might have triggered the spread of Lantana on both continents. Paradoxically, reports of Lantana control in India from the 1910s and 1920s suggest that this is also the time when the greatest effort to control Lantana was made and a variety of control measures were used (Fig. 3). South Africa did not experience such a rapid rate of change at that time possibly because Africa was still relatively isolated from extractive resource industries and large-scale intensive agriculture, e.g. [68]. South Africa, however, experienced three episodes of rapid rate of change following World War II (between 1950 and 1970). Australia also experienced a similar increase in the 1960s. Both these increases might be related to post-war land use change in

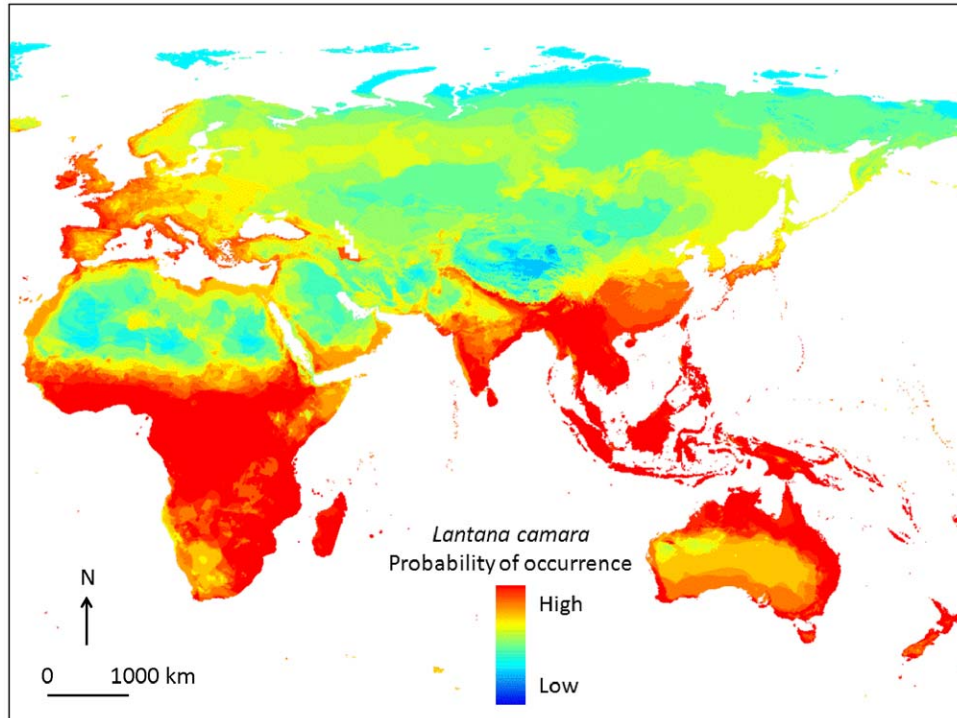

Figure 4. Bioclimatic niche model of Lantana camara based on point data stored in the Global Biodiversity Information Facility and generated by automated openModeller algorithm. The point data are derived by searching the Global Biodiversity Information Facility [90] for *Lantana camara*, which has the following recognised synonyms: *Lantana aculeata*, *Lantana tiliifolia*, *Lantana camara* var. *nivea*, *Lantana camara* var. *mista*, *Lantana camara* var. *mutabilis*, *Lantana camara* var. *hybrida*, *Lantana camara* var. *flava*, *Lantana camara* var. *aculeata*, *Lantana camara* var. *sanguinea*. The openModeller niche model uses WorldClim global climate layers (climate grids) with a spatial resolution of one square kilometre [91].
doi:10.1371/journal.pone.0032407.g004

these countries [69,70]. Such a rise is not apparent in India, possibly because the land tenure and land use in the Nilgiris, where our data comes from, has not witnessed any major changes since the 1950s [71,72]. Reports on *Lantana* control suggest that it was in the 1970s in Australia and South Africa that the greatest effort to control *Lantana* was invested (Fig. 3). While the South African trajectory continued to rise at a steady rate of change between 1970s and 2000s (possibly evidence that some of the control measures were working), Australia and India experienced another surge in 2000s (Fig. 2B). This might be a consequence of recent land use pressure on expanding agricultural sectors in both countries and consequent land use change [73,74]. These episodes of increase in the rate of change indicate the change in land use as possible driver of *Lantana* spread [75,76]. *Lantana* is a shade intolerant plant [8] and therefore any increase in the intensity of land management, e.g. increase in farmland area or opening up of forests, would have facilitated its spread. Similarly, any lapse in land management would have led to an increase in marginal lands where *Lantana* could have invaded as it is known to colonise rapidly after fire or to invade cleared grazing areas and forest plantations [7,77–79].

Role of *Lantana* in providing ecosystem function and livelihoods

The rapid spread of *Lantana* is evident from its invasion trajectory, but does this mean that its spread has always had detrimental effects on the ecosystems and the local communities who depend on them? *Lantana* has several negative impacts on ecosystems, but its positive role has also been documented. For example, while *Lantana* is known to compete with forestry species and reduce their productivity [52], it can also increase the regeneration of some non-timber forest products [12]. In addition while the presence of *Lantana*, a bee-pollinated plant [80], reduces pollinator load of native plants [81], it makes a useful honey plant [82]. *Lantana*'s toxic effects on livestock and its allelopathic effects on other plants are also well documented [47–50], however, its alkaloids are also known to have anti-bacterial, anti-microbial, anti-inflammatory, anti-tumour, and anti-AIDS properties that have the potential for use in medicine [83]. In comparison with grass-covered surfaces, *Lantana* cover can increase water run-off and, therefore, surface soil erosion, but it has also proven useful to prevent soil erosion on barren mountain slopes and in deforested areas [84,85]. Interestingly, in India, many forest managers now accept *Lantana* as a naturalised plant that plays an important role in the functioning of ecosystems by, for example, providing cover to carnivores, food for birds as well as some wild herbivores in addition to the livelihood benefits that *Lantana* provides to the local communities [86]. As such, they only aim to manage or control *Lantana* rather than attempting to eradicate it. Thus the change in management strategy from eradication to control and acceptance of *Lantana* reflects not only a realisation of the futility of eliminating *Lantana* altogether, but also increasing cognisance of its ecosystem effects, both positive and negative.

From eradication to adaptive management

The focus of *Lantana* management thus far has been on its control and eradication. As indicated by the increase in the number of reports on *Lantana* control in the 1970s, substantial effort was made to control and eradicate *Lantana* in Australia and South Africa around this time [39,40]. While the emphasis in Australia was on biocontrol [41], in South Africa mechanical removal was a preferred option [42]. Although these reports indicate substantial weed management efforts, they seem to have had little effect on the spread of *Lantana* [38,43] and it still

remains a major concern in Australia, India and South Africa [22]. The rapid invasion of *Lantana* has even instigated legislation for its control in Australia and South Africa [26,87]. This legislation restricts its import and outlines rules for its eradication. In Australia, for example, *Lantana* is a declared Noxious Weed under the New South Wales Noxious Weeds Act 1993. All *Lantana* species are declared Class 3 plants under the Land Protection (Pest and Stock Route Management) Act 2002. *Lantana* species cannot be sold or distributed and landholders may be required to control these plants if they pose a threat to an environmentally significant area in Australia [88]. Similarly in South Africa, *Lantana* is a proclaimed noxious weed under the Weeds Act (No 42, 1937), and the owner or occupier of the property is obliged to eradicate *Lantana* when such a notice has been served [30]. The Conservation of Agricultural Resources Act (1983) in South Africa has subsequently declared *Lantana* as Category 1 invasive species, which must be eradicated or effectively controlled on farm units (The Conservation of Agricultural Resources Act – Act No 43, 1983). In comparison to Australia and South Africa no such legislation exists in India, but evidence suggests that instead local communities have adapted to the presence of *Lantana*. For example, a whole new cottage industry has sprung up in areas where *Lantana* is now abundant. This includes its use in basketry; making rubbish bins, flower pots and fruit plates; thatching roofs; weaving hedges and making toys and furniture [22,89]. On a more industrial scale, *Lantana* pulp is used for making paper in India [90]. Adaptive management is an iterative, ongoing process of learning and responding to environmental conditions while acknowledging their dynamics, uncertainty, and changes over time [91]. The adaptations to *Lantana* in India represent both autonomous and planned attempts by human groups to innovate and diversify their livelihoods in response to the increasing abundance of *Lantana*. Further investigations are currently underway in the Western Ghats to see what other adaptation pathways, including practical measures of control, are being pursued by various groups in response to *Lantana*.

It is apparent that *Lantana* is an invasive plant that has adapted very well to the ecosystems it has invaded, often transforming their natural state. Furthermore, its bioclimatic niche and therefore potential for its expansion might include much more land area in Australia, India and South Africa than it has currently invaded (Fig. 4). While legislation and management have aimed at controlling the density and spread of *Lantana*, there is limited evidence for success of such control measures. The focus of legislation and management so far has been on *Lantana*'s 'ecosystem dis-services', but there is also evidence that it provides certain ecosystem services and livelihoods. Furthermore, much of the recent scientific evidence suggests that invasive species are here to stay [1,15,16,92]. For example, a long-term data set of naturalized plant species on islands [92] demonstrates that the mean ratio of naturalized to native plant species across islands has changed steadily for nearly two centuries, indicating that these new species assemblages have created novel ecosystems. In the future, conservationists and managers will need to grapple with the novel ecosystems that invasive species (such as *Lantana*) give rise to. In some areas, however, there will always be the need to control *Lantana* as it is a competitive weed, but these control measures need to be well defined and realistic. Given that the success of the eradication and management of *Lantana* has been limited thus far, better tools are needed to manage *Lantana*, possibly including more effective biological control agents. However, where such control measures are not practical, one way forward might be to embrace this pan-global invasive species and to find ways for its adaptive management.

Conclusion

Calls have been made recently for conservationists to focus on the functional role of species in ecosystems rather than their origins: “Nearly two centuries on from the introduction of the concept of nativeness, it is time for conservationists to focus much more on the functions of species, and much less on where they originated” [1], p.154. We show that in Australia, India and South Africa, despite measures to control *Lantana*, its spread and invasion have continued. We do this by developing a quantitative scale for comparison of invasion trajectories across three continents. These invasion trajectories display rapid rates of change in the 1920s, between the two World Wars, possibly due to large-scale land use changes. Even though efforts to control *Lantana* peak in India in the 1910s and in Australia and South Africa in the 1970s, this has little effect on its invasion. For most invasive species, quantitative data on historical drivers of spread are lacking and therefore development of such quantitative scale can provide a better handle on drivers of their spread. Our long-term view of *Lantana* invasion across three continents suggests that the future management of invasive species will require an adaptive management approach to their invasion. Policymakers will need to find innovative and diverse approaches to such adaptive management whilst being prepared to embrace the novel ecosystems that invasive species create and to respond to future changes in social-ecological conditions that may evolve as a result of their presence. Such an adaptive management response will be most effective to improve the resilience of both ecosystems and societies to the presence of invasive species. In the future, therefore, managers will be much better off finding new ways to adapt to invasive species rather than fighting a losing battle to eradicate them.

Materials and Methods

This investigation of *Lantana*’s invasion trajectory is based on extensive research of historical records. We followed Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines [93] to identify, screen, determine eligibility and include reports in this analysis. We systematically surveyed between October 2010 and June 2011 reports in the Bodleian Libraries in Oxford published by forestry and land management departments in Australia, India and South Africa from the 1800s until the present day. Information sources included all forestry bulletins held for each country in the Oxford libraries, all microfiche forestry resources held for each country and any other relevant forestry documents that came to light in searching through this material. For India, forestry department reports and forest working plans held at government libraries in Bengaluru, Chennai and Nilambur were also searched in addition to all issues of *Indian Forester* held at Oxford libraries.

The eligibility criteria were deliberately broad in order to ensure that we included all relevant material. For Australia and South Africa, we searched reports from all regions where *Lantana* is reported. For India, we focused on the Nilgiris region in order to understand a regional-scale perspective of *Lantana* invasion and management. All reports that mentioned weeds and their control and mentioned *Lantana* in any capacity (for example taxonomic, occurrence, control measures, status) were included in the selection process. Similarly, report on a site situated within the study area in the study countries (for example, New South Wales and Queensland in Australia; Cape to Transvaal in South Africa; and Nilgiris in India) were also included. A thorough search of these records was carried out to examine the narrative surrounding *Lantana* in each record. Notes were made using

direct quotes and paraphrasing; and any relevant citations given in reports were followed up for the verification of content.

Approximately 3000 records were thus identified through database searching (n = Australia 322; India 117; South Africa 125) and other sources (n = Australia 1350; India 173; South Africa 850). After duplicates were removed we were left with 1672 records for Australia, 290 for India and 975 for South Africa. All these records were screened for specific mention of *Lantana* and those that did not have a specific reference to *Lantana* were excluded (n = Australia 258; India 105; South Africa 100). We accessed approximately 2500 full-text articles for eligibility (n = Australia 1414; India 185; South Africa 875), again excluding those without specific reference to *Lantana*’s management (n = 26 articles for Australia, 74 for India and 45 for South Africa). We used over 2000 reports (n = Australia 1388; India 111; South Africa 830) in the qualitative synthesis. We estimate that all the reports we included in this qualitative synthesis constitute at least 75% of historical literature on the introduction, spread and management of *Lantana* in these countries.

Out of the 116 reports shortlisted for quantitative analysis, a total of 53 were from Australia, 22 from India and 41 from South Africa. These reports presented spatial and temporal dimension of *Lantana* introduction, invasion, spread and control and were included in the quantitative analysis of the invasion trajectory (Table S1A, S1B, S1C). While the historical records may present only a partial picture of *Lantana* invasion and management, in the absence of any other ecological information going back to 1800s, the historical records we used provide an important insight into the invasion, spread and management of *Lantana* over two centuries and across three continents. An additional bias is likely to be introduced because the records come from forestry departments, who are interested in eradication of invasive species due to their economic impacts. The perception of forestry departments about the threat from invasive species therefore portrays only a partial picture of *Lantana* invasion. However, in the absence of long-term historical ecological studies to verify such qualitative reports, we considered our semi-quantitative approach to be a pragmatic solution for an enhanced understanding of invasive species and their management.

To examine regions in Australia, India and South Africa that are affected by *Lantana* invasion, we plotted geographical co-ordinates for locations of all available reports (Fig. 1A, 1B, 1C). Where only place names were available, we derived geographical co-ordinates from Google Maps. We colour-coded these point data for each decade between 1900 and the present day. Very few records were available for the time period between 1800 and 1900, so we grouped these records into ‘pre-1900’ category.

The narratives of *Lantana* invasion included its mention as an ornamental plant, popular hedge plant, its spread as invasive; and the managers’ success or failure to control it. A scale of 1–7 was used to score records along increasing severity of *Lantana* invasion (Fig. 2A): (1) first introduced; (2) present, but not a problem; (3) considered weed, invasive or noxious plant; (4) management intensified; (5) management reported effective in some areas; (6) continuation of same management strategy; (7) *Lantana* seen to be spreading in spite of management. The qualitative narratives were scored independently by two of the authors (EB and TT) to ensure that there is consistency in scoring. When scoring, the earliest record for each category was used to determine the timing to move up the scale. As such, ‘first introduced’ reflects the introduction of *Lantana* as ornamental plant and ‘present but not a problem’ reflects later narratives which do not yet refer to the plant as an invasive or weed, but report the presence of *Lantana* in the wider landscape beyond the areas where it was planted. Further up the

scale, Lantana is considered a weed, invasive or noxious plant and is referred to as a problem. Management intensification reflects concerted effort by government authorities to control and manage the weed. Further up the scale, management is reported effective in some areas reflecting reports of management success. The continuation of the same management strategy is categorised as a separate entity because government agencies report using the same management strategy in the broader landscape, as opposed to intensifying management further. The final category, which reflects the spread of Lantana despite management captures reports of frustration from the government authorities that this weed is beyond control or management. The quantitative scale we devised allowed synthesis of anecdotal information reported in historical records and comparison of Lantana narratives across the three countries. The two authors (EB and TT) who scored each record independently arrived at the same score in 95% of the cases, indicating that our seven categories of the scale of invasion are robust. Where judgements differed, the two authors conferred their score before including it in the quantitative scale.

Based on this quantitative scale of Lantana invasion, we calculated rate of change per year (Fig. 2B) such that a sharp increase in the scale of invasion over time indicated high rate of change and slow increase in the scale of invasion indicated a low rate of change. A comparison of the rates of change allowed identification of time periods that coincided with rapid spread of Lantana.

To compare effort spent on controlling Lantana across the three countries, we examined the variety of methods reported for Lantana management. These methods were categorised into five classes: fire, mechanical, chemical, biocontrol and combination of all methods. We calculated percentage of total reports in each decade that mentioned each of these methods (Fig. 3).

To identify a potential bioclimatic envelop for Lantana, we used point data for *Lantana camara* (and synonyms) in Global Biodiversity Information Facility [94] and developed a global niche model for Lantana with automated openModeller algorithm, which uses WorldClim climate layers [95]. For each given climate variable the algorithm finds the minimum and maximum value at all sites of occurrence. The probability of occurrence is determined as: $p = \text{layers within min-max threshold} / \text{number of layers}$, e.g. [96] (Fig. 4).
